## **Explanations**

SAMPLE

**1. What term refers to how high or low a tone is perceived by the human ear?**

- A. Frequency**
- B. Pitch**
- C. Loudness**
- D. Amplitude**

The term that refers to how high or low a tone is perceived by the human ear is known as pitch. Pitch is directly related to the frequency of sound waves, which is measured in hertz (Hz). Higher frequencies are perceived as higher pitches and lower frequencies as lower pitches. This perception allows humans to distinguish between different musical notes and tones. Frequency, while closely related to pitch, specifically describes the number of sound wave cycles that occur in one second and does not account for our perception of sound. Loudness refers to how intense or strong a sound is perceived, and it is more related to the amplitude of the sound waves rather than their frequency. Amplitude measures the height of the sound wave, indicating how much energy the wave possesses, which influences loudness but not pitch. Therefore, pitch is the most accurate term for the subjective perception of the height or depth of a sound.

**2. Which SI unit measures the difference in electric potential?**

- A. Amperes**
- B. Watts**
- C. Volts**
- D. Ohms**

The SI unit that measures the difference in electric potential is the volt. Electric potential, often referred to as voltage, represents the work done per unit charge in moving a charge between two points in an electric field. Essentially, it quantifies the potential energy available to push electric charges through a circuit. When a difference in electric potential exists, it indicates how much energy is needed to move a charge from one point to another, making it a fundamental metric in understanding electrical circuits and systems. The volt is defined as one joule per coulomb, emphasizing the relationship between energy and charge. In contrast, amperes measure the flow of electric current, watts measure power (the rate at which work is done or energy is transferred), and ohms indicate electrical resistance. These units play vital roles in electrical calculations but do not measure electric potential itself. Thus, volts is the correct choice for the unit that reflects the difference in electric potential.

### 3. What materials are known to produce a magnetic field naturally?

- A. Paramagnetic materials**
- B. Diamagnetic materials**
- C. Ferrimagnetic materials**
- D. Superconductors**

Ferrimagnetic materials are known to produce a magnetic field naturally due to the alignment of magnetic moments of atoms in opposite directions, but not completely cancelling each other out. In ferrimagnetic materials, such as magnetite ( $\text{Fe}_3\text{O}_4$ ), there are two different types of iron ions that have different magnetic moments, leading to a net magnetization. This property allows these materials to maintain a permanent magnetic field even in the absence of an external magnetic field. Paramagnetic materials can be magnetized in the presence of an external magnetic field but do not retain any magnetization once the external field is removed. Although they do respond to magnetic fields, they do not produce a magnetic field on their own. Diamagnetic materials are characterized by their ability to be repelled by magnetic fields and do not have any permanent magnetic dipole moment. They create an induced magnetic field in a direction opposite to an applied magnetic field but do not produce a magnetic field naturally. Superconductors, while they can exhibit perfect diamagnetism and repel magnetic fields, only do so under specific conditions that involve extremely low temperatures. They do not produce a magnetic field naturally in the same sense as ferrimagnetic materials do under standard conditions. Therefore, among the given choices,

### 4. What is the definition of a resistor in an electrical circuit?

- A. An object that speeds up electron flow**
- B. An object that stores electric charge**
- C. An object that impedes the flow of electrons**
- D. An object that generates voltage**

The definition of a resistor in an electrical circuit is that it is an object that impedes the flow of electrons. Resistors are essential components that limit the current that can flow through a circuit, allowing for the control of electrical energy. By providing resistance, they convert some of the electrical energy into heat, which is why they often become warm during operation. This property is crucial for protecting sensitive components in a circuit by preventing excessive current that can lead to damage. The other options suggest functions that do not align with the primary role of a resistor. For instance, an object that speeds up electron flow would not be classified as a resistor, as resistors inherently slow down the flow of current. Similarly, an object that stores electric charge refers to capacitors, while an object that generates voltage typically describes a power source, such as a battery or generator. Thus, the characteristic of impeding electron flow accurately captures the fundamental function of a resistor in electrical circuits.

**5. Which color of light has a wavelength longer than ultraviolet light?**

- A. Red**
- B. Blue**
- C. Green**
- D. Infrared**

The correct choice is infrared because it falls within the electromagnetic spectrum at wavelengths longer than ultraviolet light. Ultraviolet (UV) light has wavelengths ranging from about 10 nm to 400 nm, while infrared light begins just after the visible spectrum, typically starting around 700 nm and extending to about 1 mm. This positioning means that infrared light has significantly longer wavelengths than ultraviolet light. In contrast, red, blue, and green light belong to the visible portion of the spectrum, with red light having the longest wavelength among the three but still shorter than infrared. Red light ranges from about 620 nm to 750 nm, blue light ranges from about 450 nm to 495 nm, and green light is between approximately 495 nm and 570 nm. Therefore, infrared light is the only color listed that has a wavelength longer than that of ultraviolet light.

**6. What term is used to describe the number of cycles per second for waves?**

- A. Amplitude**
- B. Frequency**
- C. Wavelength**
- D. Period**

The term used to describe the number of cycles per second for waves is frequency. Frequency quantifies how often a wave oscillates or completes a full cycle in one second and is measured in hertz (Hz). When discussing waves, frequency is an essential concept because it directly relates to the energy and characteristics of the wave. In contrast, amplitude refers to the height of the wave and is associated with the wave's intensity or strength, whereas wavelength is the distance between successive crests (or troughs) of a wave, relating to its spatial characteristics. The period is inversely related to frequency; it represents the time it takes for one complete cycle of the wave to pass a given point. Since frequency and period are related by the equation  $(\text{Frequency}) = \frac{1}{(\text{Period})}$ , understanding frequency helps in analyzing the behavior of waves across various contexts.

## 7. What is the SI unit used to measure frequency?

- A. Joule (J)**
- B. Hertz (Hz)**
- C. Watt (W)**
- D. Newton (N)**

The SI unit used to measure frequency is Hertz (Hz). Frequency refers to the number of cycles of a periodic wave that occur in one second. Specifically, one hertz is defined as one cycle per second. This measurement is critical in various fields, such as physics and engineering, where understanding oscillations, waves, and alternating currents is essential. The other units mentioned are associated with different physical quantities. For instance, the joule measures energy, the watt measures power, and the newton measures force. Each has its distinct application, but they are not related to the measurement of frequency. Understanding these distinctions helps clarify the specific role that Hertz plays in the broader context of physical measurements.

## 8. What is the term for the quietest sound that can be detected by the human ear?

- A. Threshold of Hearing**
- B. Threshold of Pain**
- C. Sound Barrier**
- D. Decibel Level**

The term that refers to the quietest sound that can be detected by the human ear is known as the "Threshold of Hearing." This concept is critical in the study of sound and human perception, as it represents the minimum intensity of sound that can be perceived by an average human without any other noise. At this threshold, sound waves have a certain pressure level, typically around 0 decibels (dB), which is a reference point in acoustic measurements. Understanding the Threshold of Hearing provides insight into human auditory capabilities and is foundational in fields such as audiology and sound engineering. Other options, while related to sound and hearing, refer to different concepts. The Threshold of Pain indicates the intensity level at which sound becomes painful, the Sound Barrier refers to the speed of sound and the challenges associated with surpassing it, and Decibel Level pertains to the measurement of sound intensity in a logarithmic scale rather than identifying the quietest sound detectable. Each of these terms serves a specific purpose within the study of sound but does not define the quietest perceivable sound like the Threshold of Hearing does.

**9. What defines the angle formed by a ray and the normal line at the point of incidence?**

- A. Angle of reflection**
- B. Angle of refraction**
- C. Angle of incidence**
- D. Critical angle**

The angle formed by a ray and the normal line at the point of incidence is defined as the angle of incidence. This angle is crucial in understanding how light interacts with different mediums, as it describes the angle at which a light ray strikes a surface compared to an imaginary line called the normal, which is perpendicular to that surface at the point of contact. When a ray of light strikes a surface, the angle of incidence is measured from the incoming ray to the normal line. This is significant because it directly correlates to the other angles that arise during reflection and refraction. For instance, the angle of reflection, occurring after a ray bounces off a surface, is equal to this angle of incidence, in accordance with the law of reflection. Similarly, when light passes from one medium to another, the angle of refraction is influenced by the angle of incidence according to Snell's law. The critical angle refers to a specific scenario in which light is completely reflected within a medium, and it only applies when light travels from a denser to a less dense medium. Therefore, the angle that specifically defines the relationship at the point where light first intersects with a surface is indeed the angle of incidence.

**10. What is generated by the interaction of light with matter?**

- A. Image**
- B. Photon**
- C. Wave**
- D. Ion**

The interaction of light with matter generates various phenomena, depending on the context of that interaction. The generation of an image occurs when light reflects off surfaces or is absorbed and re-emitted by materials, allowing our eyes to perceive shapes, colors, and forms. This is especially relevant in optics, where light interacts with lenses and surfaces to create images that can be focused, magnified, or manipulated. The other choices address different concepts. For instance, photons are the elementary particles of light itself, and while they are involved in interactions with matter, photons are not the product of that interaction in the way an image is. A wave refers to the behavior of light as a wave in specific contexts, but again, it does not encapsulate the outcome of the interaction with matter like an image does. Ions are charged particles typically formed from the loss or gain of electrons by atoms; while light can influence ion formation in specific interactions such as photoionization, this is not the most direct or relevant outcome when considering everyday interactions of light with matter. Thus, generating an image is the most straightforward and applicable result of light interacting with matter.
